DENOISING AND DEINTERLEAVING OF EPSI DATA USING STRUCTURED LOW-RANK MATRIX RECOVERY

Ipshita Bhattacharya, Mathews Jacob

ABSTRACT

Echo-planar spectroscopic imaging (EPSI) sequence with spectrally interleaving is often used to rapidly collect metabolic MRI data. The main problem in using it on high field scanners is the presence of spurious peaks resulting from phase distortions between interleaves as well as the low signal to noise ratio. We introduce a novel structured low-rank framework for the simultaneous denoising and deinterleaving of spectrally interleaved EPSI data. The proposed algorithm exploits annihilation relations resulting from the linear predictability of exponential signals as well as due to uncorrected phase relations between interleaves. The algorithm is formulated as a structured nuclear norm minimization of a block Hankel matrix, derived from the interleaves. Experiments using hyperpolarized $^{13}$C mouse kidney EPSI data demonstrate the ability of the algorithm to remove ghost peaks from EPSI data collected using bipolar readout gradients.

Index Terms— echo planar spectroscopic imaging, odd and even echoes, ghost peaks, structured low-rank recovery

1. INTRODUCTION

Shortening scan time has been a prime focus of magnetic spectroscopic imaging (MRSI) research [1, 2]. EPSI [3, 4] achieves accelerated data acquisition by using echo-planar readouts to simultaneously encode one spectral and one spatial dimension in one acquisition. This approach offers a speed up that is equal to number of points along one spatial dimension. However, it imposes high demands on the gradient system to maintain sufficient spectral resolution on high field systems that have greater spectral dispersion. A common practice to achieve sufficient spectral resolution is spectral interleaving, where the readouts are delayed in time for each spectral interleave. The data from multiple interleaves are upsampled and interlaced to form the final spectrum. A challenge associated with this strategy is the phase inconsistencies between interleaves, resulting from timing errors in the applied gradient trains, drifts in the magnetic field, and dependence on field inhomogeneity distortions. This problem is similar to Nyquist ghosting artifacts in echo-planar imaging (EPI), which manifests as Nyquist ghosts in the phase encoding dimension. In EPSI acquisitions, the phase inconsistencies manifest as spurious peaks in the spectra, which often makes the interpretation of the data challenging. Specifically, the proximity of a spurious peak from a strong metabolite may result in lineshape changes, affecting the accurate quantification of a relatively weak metabolite. Likewise, the intensity of the true peak may also be reduced since the energy is split between the true peak and ghost peak.

Several methods have been developed for the reduction of spectral ghosts in EPSI data. The conventional approach processes the odd and even echoes separately [6] reducing the spectral bandwidth by half; hence is not an option for high field scanners. Methods relying on theoretical estimates of k-t space trajectory such as the interlaced Fourier transform method [7] or the Fourier shift method [8] ignore the phase distortion between the echos. Echo misalignment [6, 7] correction has shown good potential in the reduction of spurious peaks, contingent to accurate estimation of k-t space trajectory that is often not practical in the presence of drifts and $B_0$ inhomogeneity. Another popular method is to estimate the phase inconsistencies from the center of k-space and correct for the misalignment between the echoes [5] during data processing. Even though this method has shown promise in fat-water imaging, its utility for low-intensity metabolites is yet to be seen.

We introduce a novel reconstruction method for EPSI data which does not depend on accurate estimates of phase inconsistencies or k-t space trajectory to suppress the spectral ghosts. We exploit the annihilation relations in spectrally interleaved EPSI data resulting from the linear predictability of exponential signals and phase relations between the interleaves. We pose the problem as a recovery of two signals at each pixel, corresponding to the odd and even interleaves. Experiments using hyperpolarized $^{13}$C mouse kidney EPSI data demonstrated the ability of the algorithm to remove ghost peaks from EPSI data collected using bipolar readout gradients.

This work is supported by grants NSF CCF-1116067 and ONR-N000141310202. The data used in the study was provided by Hansol Lee and Dong-Hyun Kim of Yonsei University College of Medicine, Seoul, Republic of Korea.
Unfortunately, the signal formation is shown in Fig.1. The Fourier transform of the signal along \( f_k \) is the basic goal in MR spectroscopy to estimate the amplitudes \( c_k \) from the data. Since the bandwidth of the spectrum is too large in high field scanners, it is often impossible to sample the signal at the Nyquist rate using EPSI. It is a common practice to acquire the data using spectral interleaving, where the signal is sampled twice with a sampling interval of \( 2T \). Specifically, one would acquire two signals \( \rho_o[n] \) and \( \rho_e[n] \), where the read-out of the odd signal is delayed by \( T \). These signals are later combined as

\[
\rho_{\text{combined}}[n] = \begin{cases} 
\rho_e[n] & \text{if } n \text{ is even} \\
\rho_o[n] & \text{if } n \text{ is odd}
\end{cases}
\]

Unfortunately, \( \rho_e \) and \( \rho_o \) are acquired at two different acquisitions and hence would differ in terms of a phase distortion. The distortion is often a complex function of the readout delay \( T \) and the field inhomogeneity at the spatial location \( r \). Hence, the combined signal (4) often suffers from spectral ghosts, shifted from the original point by N/2 spectral points; the distribution of the amplitudes to the two peaks is depend-ent on the phase distortion. A schematic diagram explaining the signal formation is shown in Fig.1.

2. BACKGROUND

We assume that the true spectrum at a specified pixel \( r \) as a multi-exponential model:

\[
\rho[r, n] = \sum_{k=1}^{K} c_k[r] (\nu_k)^n; \quad n = 0, \ldots, N - 1
\]

where \( K \) is the number of exponentials with parameters

\[
\nu_k = \exp \left\{ - \left( \frac{1}{\tau_{2,k}} + j2\pi f_k \right) T \right\},
\]

and \( c_k \) are amplitudes. Here \( \left( \frac{1}{\tau_{2,k}} + j2\pi f_k \right) \) are the exponential parameters of the \( k^{1\text{st}} \) exponential and \( T \) is the Nyquist sampling interval. We will omit the dependence of the signal on the spatial location for simplicity in the future discussions. The Fourier transform of the signal along \( n \), specified by

\[
\hat{\rho}[k] = \sum_{n=1}^{N} \rho[n] \exp \left( -j \frac{2\pi}{N} kn \right)
\]

will have \( K \) peaks at frequencies \( f_k \); the basic goal in MR spectroscopy is to estimate the amplitudes \( c_k \) from the data.

Since the bandwidth of the spectrum is too large in high field scanners, it is often impossible to sample the signal at the Nyquist rate using EPSI. It is a common practice to acquire the data using spectral interleaving, where the signal is sampled twice with a sampling interval of \( 2T \). Specifically, one would acquire two signals \( \rho_o[n] \) and \( \rho_e[n] \), where the read-out of the odd signal is delayed by \( T \). These signals are later combined as

\[
\rho_{\text{combined}}[n] = \begin{cases} 
\rho_e[n] & \text{if } n \text{ is even} \\
\rho_o[n] & \text{if } n \text{ is odd}
\end{cases}
\]

Unfortunately, \( \rho_e \) and \( \rho_o \) are acquired at two different acquisitions and hence would differ in terms of a phase distortion. The distortion is often a complex function of the readout delay \( T \) and the field inhomogeneity at the spatial location \( r \). Hence, the combined signal (4) often suffers from spectral ghosts, shifted from the original point by N/2 spectral points; the distribution of the amplitudes to the two peaks is dependent on the phase distortion. A schematic diagram explaining the signal formation is shown in Fig.1.

3. METHODS

We introduce an algorithm for the removal of spurious peaks as well as the denoising of spectroscopic MRI data. The algorithm exploits the annihilation relations induced by the spectral model (1) as well as the phase relations in (5) & (6). We use a lifting strategy, where a structured matrix is formed using the entries of the measured signals \( \rho_e \) and \( \rho_o \) to exploit the annihilation relations. The rank of the structured matrix is very low due to the annihilation relations. We use the low-rank property to jointly recover the fully sampled signals \( \rho_e[n] \) and \( \rho_o[n] \) from their undersampled measurements.

We model the phase distortions in \( \rho_e \) and \( \rho_o \) as convolutions by finite impulse response filters \( g_e[n] \) and \( g_o[n] \), respectively. Specifically, we assume that

\[
\hat{\rho}_e[k] = \hat{\rho}[k] \hat{g}_e[k]
\]

\[
\hat{\rho}_o[k] = \hat{\rho}[k] \hat{g}_o[k],
\]

where the signals \( g_e[k] \) and \( g_o[k] \) are specified by

\[
g[k] = \sum_{m=-M}^{M} c[k] \exp \left( -j \frac{2\pi pk}{N} \right)
\]

Note that the above model can easily account for differences in phases and differences in frequencies in a small range determined by \( T \), between the two acquisitions.

3.1. Annihilation relations induced by exponential model

Exponential signals in (1) satisfy an annihilation relation [12, 13]:

\[
\rho[n] * h[n] = 0,
\]

where \( h \) is the FIR filter of the form

\[
h(z) = \prod_{i=1}^{K} (1 - \nu_i z^{-1}).
\]

Since \( \rho_e(z) = \rho(z) h_e(z) \) and \( \rho_o = \rho(z) h_o(z) \), both of these signals also satisfy (8) with the same filter. The convolution relation in (8) can be expressed as in the matrix form as \( Q_e h = 0 \) and \( Q_o h = 0 \), where \( Q_e \) and \( Q_o \) are \( (N - K + 1) \times K \) dimensional Hankel matrices formed from the samples of \( \rho_o \) and \( \rho_e \), respectively. In reality, the number of exponentials \( K \) is unknown, when one can overestimate it as \( P \). In this case, any filter specified by \( h_n(z) = h(z) \eta(z) \) such that \( h_n \) is a \( P \) tap filter also annihilates the signal. Since one can find \( P - K \) linearly independent filters \( \eta(z) \), the rank of the \( (N - P + 1) \times P \) dimensional matrices \( Q_o \) and \( Q_e \) can be shown to be equal to \( K - 1 \) (see [12] for details).

3.2. Annihilation property induced by phase relations

The model specified by (6) and (5) implies that there exists annihilation relations between the two signals

\[
\rho_e[n] * g_o[n] - \rho_e[n] * g_e[n] = 0.
\]
use root mean square of $\mu_o$ & $\mu_e$ as the recovered spectrum. Since exponential signals with fewer exponential parameters are associated with lower rank, the proposed formulation performs simultaneous denoising and deinterleaving.

The periodic undersampling pattern that results from interleaved sampling may result in a trivial solution, if the spectral annihilation relations are not exploited [11]. Specifically, the trivial solution $\mu_o = \rho_{\text{combined}} = \mu_e$ will satisfy the data consistency relations and the trivial annihilation relation $\mu_o[n] \ast \delta[n] - \mu_e[n] \ast \delta[n] = 0$, resulting in a matrix of rank $P$. However, when the signal follow a multiexponential model as in (1), we observe that the trivial solution has $2K$ (double the number of exponential parameters), when compared to the true solution due to aliasing. This shows that the trivial solution is not the one that satisfies the data consistency constraints and yield the minimum rank of $Q$.

### 3.3. Proposed structured low-rank algorithm

We use the low-rank structure of $Q$ to recover the two signals $\mu_o$ and $\mu_e$ from their undersampled measurements:

$$\{\mu_o, \mu_e\} = \arg \min_{\mu_o, \mu_e} \| A_o \mu_o - \rho_o \|^2 + \| A_e \mu_e - \rho_e \|^2 + \lambda \| \{ T(\mu_o), T(\mu_e) \} \|_*$, \hspace{1cm} (13)$$

where $A_o$ and $A_e$ are undersampling operators corresponding to $\rho_o$ and $\rho_e$, respectively. We use an iteratively reweighted nuclear norm minimization algorithm to minimize the above cost function and recover the signals. Post recovery, we will

#### 4. EXPERIMENTS AND RESULTS

A 9.4T small animal imaging scanner (Bruker BioSpin MRI GmbH, Germany) equipped with $^1H-^{13}C$ dual-tuned mouse volume Tx/Rx coil was used for all experiments [15]. $[1-^{13}C]$ pyruvic acid doped with 15mM Trityl radical and 1.5M Dotarem was polarized for 1 hour using HyperSense DNP polarizer (Oxford Instruments, Oxford, UK). Hyperpolarized sample was dissolved with Tris/EDTA-NaOH solution, and 350ul of pyruvate was injected into Balb/c mouse through tail vein catheter over duration of 5s. Axial oriented slice containing mouse kidney of 3 mm thickness was selected, and the scan was started at 5s after injection of the pyruvate. All procedures of the animal experiments were approved by the local animal care and use committee. EPSI data of matrix size 64 $\times$ 64 was collected using a bipolar gradient with 64 spectral points. Combination of odd and even echoes achieved a spectral bandwidth of 1562.5 Hz.

We compared the algorithm with phase correction method [5]. In Fig.2(a) the reference $^1H$ image with three reference pixels are shown. Fig.2(b-d) & (f-g) show the spurious peak frame and pyruvate maps for all methods. The spurious peak frame shows reduced intensity for the proposed method which corresponds to improved removal of spurious peaks. The proposed method shows improved signal concentration for the pyruvate maps in areas as shown by the arrows. The percentage difference map in Fig.2(e) shows up to 70% increased signal recovered by the proposed method compared to the uncorrected data.

The spectra in Fig.3 from three regions of the kidney (aorta, cortex & medulla) show complete removal of spurious peaks and also exhibits denoising. The phase correction provides no denoising and also has sub-optimal performance especially for the renal medulla (blue) pixel.

### 5. CONCLUSION

In this work we proposed a novel algorithm for denoising and deinterleaving of EPSI data without directly estimating
phase or relying on theoretical k-space trajectory. We further demonstrated the improvement offered by the proposed method compared to the classical phase correction method. The proposed scheme would be highly beneficial in reconstruction and correction of high-resolution EPSI, especially for the acquisition from high field magnets.
